

What is it ?

- A trie is a tree-like data structure used for efficient retrieval and autocomplete functionality, where each path from the root to a node represents a word or prefix
- A trie can mark a complete word by either adding a special 'asterisk' child or by using an Boolean flag on the node representing the last character of the word.
- A depth-first search (pre-order traversal) can be used to retrieve words in a trie in alphabetical order

Complexity

- Trie lookup is considered $O(1)$ or constant time, as the lookup time is bounded by the maximum length of words in the dictionary, not the total number of words stored.
